Abstract

Our ability to recognise complex images across contexts depends on our exposure to similar 12 instances. For example, despite much natural variation, it is easier to recognise a new 13 instance of a familiar face than an unfamiliar face. As we encounter similar images, we 14 automatically notice structural commonalities and form a representation of how the image 15 generally looks, even when each image is presented rapidly (i.e., several milliseconds each). 16 However, it is not clear whether this process allows us to better identify new instances of an 17 image compared to assessing single images for a longer duration. Across two experiments, I 18 tested observers' person recognition ability when presented with rapid image streams at 19 varying rates compared to a single image. Experiment 1 compares performance between 20 upright and inverted faces. Experiment 2 compares performance between fingerprints from 21 the same finger and from the same person more generally. My results suggest that viewing 22 images rapidly is better than single images when identifying faces, but not fingerprints; and that people better recognise upright compared to inverted faces, but are similar in both fingerprint conditions. I discuss the theoretical implications of these results, as well as some practical implications in security and forensic contexts.

Significance Statement

Forensic examiners in various fields are regularly required to make identification 70 decisions based on complex, unfamiliar images – such as a stranger's face, or a stranger's 71 fingerprint – often based on a single comparison photo, or a limited number of comparison photos. While much evidence suggests that recognising a new image would benefit from 73 viewing multiple different examples of that image beforehand, fewer studies have explored whether it is more beneficial to view several comparison photos quickly, or a single comparison photo for a longer duration, if given a limited time to make the identification. If 76 quickly processing several images leads to greater image recognition, then a similar approach 77 could be used to better allocate time resources, or streamline training in many forensic 78 identification disciplines. In this study, we tested this idea under various different conditions, 79 using face (Experiment 1) and fingerprint (Experiment 2) stimuli, with novice participants. While we speculated on many possible constraints when applying this methodology under 81 different conditions, we generally found that while there was an advantage to quickly viewing 82 several images, this advantage was more pronounced with more familiar image categories, 83 and was slightly affected by image specificity. 84

85 Introduction

- [Fix up expression]
- [Make sure all links to OSF pages are working]
- [Make sure all references are done...]
- Our ability to correctly categorise an object or image seems to depend on how much experience we have in viewing similar kinds of objects in the first place. For example, the

prototype theory of categorisation suggests that when categorising an object, we compare it to the typical representation of similar objects in our long-term memory and categorise it accordingly (reference). Similarly, the exemplar theory of categorisation suggests that, when 93 recognising an object, we compare it to our memories of specific objects within a particular category that we have accumulated in the past (references), and search for similarities. Due 95 to this reliance on similar prior experiences, it tends to be more difficult to categorise objects that we do not see very often, because we are not familiar with how these objects may vary 97 under different contexts, or are unaware of the more stable, average characteristics among these objects that may facilitate categorisation (reference). On the particular level, for example, a substantial body of literature has focused on the role of familiarity in individual 100 face recognition. Indeed, trying to identify a stranger's face proves much more difficult than 101 identifying a friend's face or a celebrity's face, because we do not know what a stranger's face typically looks like and how it varies across contexts, and may mistake simple variations 103 in lighting or hairstyle for complete changes in identity (references). This is not the case for familiar faces, where we can remember their stable facial features across contexts, and can 105 easily recognise those features even in a new environment (references). However, even if we 106 do not have exposure to various instances of the same object, evidence suggests that our 107 cumulative experience in viewing various instances of the broader category can still yield an 108 advantage. Fingerprint experts, for example, can better identify two unfamiliar fingerprints 109 compared to novices because their vast experience with fingerprints generally allows them to 110 better understand how fingerprints vary. 111

If our ability to effectively recognise and categorise different objects, both on an individual and categorical level, is assisted by our understanding of the commonalities between members of a particular category, how then do we make sense of these commonalities? One related explanation is "ensemble coding", which allows us to glean the average properties of a range of similar stimuli and automatically make sense of the common characteristics in our environment (references). However, while the previous studies in

identification and categorisation may suggest that learning regularities among a category depends on having ample exposure to each individual instance - for example, face recognition 119 studies often give participants several seconds to learn new faces (references), and fingerprint 120 (reference) experts will have spent hours in cumulatively viewing objects in their domain of 121 expertise - research in ensemble coding suggests that committing each instance to visual 122 memory over time may not even be necessary. In fact, many studies using the rapid serial 123 visual presentation (RSVP) methodology, where a series of similar images are presented for 124 several milliseconds each one after the other, have shown that we can automatically compute 125 the average representation of all of the images - despite not being able to process any 126 individual image. This finding has been replicated for when participants focus on simple 127 stimuli (e.g., average circle size; reference), complex stimuli (e.g., average facial expression; 128 reference), and even when the RSVP stream is not the main focus of the experiment (reference). However, while ensemble coding is very robust to task demands, and it seems 130 intuitively linked to how we become familiar with a set of images, no studies seem to have established whether presenting unfamiliar images in an RSVP stream can help to identify 132 new images of the same category. The current study, therefore, asks whether rapidly viewing 133 the gist of several images can improve novices' ability to identify unfamiliar objects compared to carefully assessing the details of a single image, using strangers' faces and 135 fingerprints as visual stimuli. 136

Previous research has suggested that exposing novices to several instances may better simulate expertise than only assessing single images (double check if this is true - Thompson & Tangen, 2014), and so this may be a powerful methodology to do so. However, previous research has also suggested that visual expertise has its limits (Bukach, Phillips & Gauthier, 2010; Diamond & Carey, 1986; see and include Searston & Tangen, 2017), and so we will also explore the possible constraints to this methodology when considering other variables that may influence recognition in these contexts.

47 The Current Study

The present research examines whether viewing an RSVP stream of images at varying 148 rates can better facilitate object recognition compared to viewing a single image, when 149 presented for an equal duration of time. While several studies on face recognition have 150 already suggested that it is better to view more photos of a person compared to fewer photos 151 (e.g., Murphy et al., 2015), no studies seem to have directly compared whether it is better to 152 carefully assess the details of a single image, or the get the general gist of several images 153 rapidly, when making an identification - and so our study will be the first to do so. Across 154 two experiments, we presented participants with complex, unfamiliar images representing the 155 same person (i.e., a stranger's face or fingerprint), as either single images, or as RSVP 156 streams at varying rates (i.e., two, four, and eight images per second) for a total of eight 157 seconds. In each trial they were asked whether they viewed images from the same or 158 different category to the test image (e.g., "Is this the same person?"). Based on previous 159 research, we expect that recognition performance will increase as participants view more 160 images per second, given that this would allow them to create richer ensemble representations compared to other conditions. In essence, viewing more images per second 162 may allow participants to become "more familiar" with the unfamiliar stimuli presented, making it easier to recognise any common features shared with the test image and make an 164 appropriate identification or rejection. 165

In Experiment 1, participants view the RSVP streams *before* viewing the test image, as
previous research suggests (references) that it is the accumulation of multiple previous
exemplars that facilitates face recognition. We will also explore whether recognition in these
different conditions is affected by familiarity with the general stimulus class, by presenting

the faces as upright and inverted images. Previous research in visual recognition has 170 suggested that we are much better at recognising upright faces compared to inverted faces 171 (see Rossion, 2008 for a review) - possibly due to our disproportionate experience in viewing 172 upright faces everyday (references), an innate ability to do so more efficiently (references), or 173 a combination of both. In manipulating face inversion in this experiment, we can examine 174 the influence of ensemble coding in recognition tasks not only on an individual level of 175 familiarity, but on a group level: if ensemble coding tends to be automatic and accurate 176 when viewing simple stimuli (e.g., circle size; references) and complex familiar stimuli (e.g., 177 upright faces; references), would it operate the same way when viewing complex unfamiliar 178 stimuli (i.e., inverted faces)? It is possible that inverted faces may not share the same benefit 179 as upright faces, as the difficulties in processing inverted faces holistically (Tanaka & 180 Simonyi, 2016; see also Rossion, 2008 for a review) may make it more difficult to process the gist of each image in the stream. However, given how automatic ensemble coding is in a 182 variety of tasks with a variety of stimuli, we believe that our methodology could nevertheless 183 exert a positive influence with face recognition (but see Haberman et al., 2009; Haberman, 184 Lee, & Whitney, 2015; and Leib, Puri, Fischer, Bentin, Whitney, & Robertson, 2012, in 185 relation to ensemble coding generally - what have these studies said???). In fact, we predict 186 that any benefit derived from ensemble coding may actually be more pronounced when 187 viewing inverted compared to upright faces, given that our existing advantage for upright 188 face-matching may limit how beneficial this methodology may be for upright faces relative to 189 inverted faces, which do not share the same constraints. Additionally, we expect that upright 190 face recognition may also be constrained by the flashed-face distortion effect (FFDE), where 191 faces in an RSVP stream (particularly at a rate of 200-250ms) have been reported to appear 192 distorted as the relative differences between facial features from one image bleed into the 193 next (Tangen, Murphy, & Thompson, 2011). Given that this effect seems to require holistic 194 processing and is less prominent in inverted faces (Bowden, Whitaker, & Dunn, 2019; 195 Tangen et al., 2011), it is possible that it may distract from our ability to correctly identify 196

upright faces when presented at certain rates in a rapid stream.

Experiment 2 employs a similar design to Experiment 1; however, to more closely 198 resemble fingerprint identification procedure, participants were shown the target image of a 199 crime scene print first, before viewing the RSVP stream or single comparison print. While 200 this may change the nature of how beneficial the subsequent ensemble representation may be, 201 previous research using the RSVP methodology suggests that when participants are primed 202 to recognise a particular image among a subsequently presented image stream of random 203 images, performance improves drastically (reference), as they now know what to look for. Accordingly, similar to Experiment 1 we predict that performance will improve when viewing more rapid image streams. Additionally, instead of presenting fingerprints in an upright or inverted orientation as in Experiment 1, our conditions manipulated whether participants 207 viewed fingerprints belonging to the same finger (i.e., "Is this John's thumb?"), or to the 208 same person more generally (i.e., "Does this fingerprint belong to John?"), as this 209 manipulation will allow us to simulate the kinds of 'ten-print' materials that fingerprint 210 examiners typically have at their disposal (reference). In doing so, we can examine whether 211 the potential benefits of an RSVP stream are constrained by the specificity of the 212 identification. While evidence suggests that novices may perform similarly when 213 discriminating prints from the same person and same finger (Searston & Tangen, 2017c; 214 Tangen et al., 2011; Tangen et al., 2014), RSVP streams consisting of the same finger prints 215 may contain less variation compared to prints from different fingers from the same person, 216 and therefore may generate a more stable ensemble with which to compare the latent print 217 (see Whitney & Leib, 2018), making recognition easier. We therefore predict that any 218 benefits derived from the RSVP methodology may be more pronounced when viewing 219 streams of the same finger.

In both experiments, while recognition accuracy may be higher when viewing more images, we expect that confidence may be higher when viewing *fewer* images, as these

conditions would likely feel the most intuitive to participants, and would allow participants to maximise the encoding of any particular details.

Experiment 1

$_{26}$ Methods

225

The preregistration plan [add link] for both experiments is available on the Open Science Framework (OSF), and includes our predictions and hypotheses, methodology, power analysis, analysis plan, and links to all available materials, software, raw data files, and R markdown scripts.

Participants. 30 participants took part in this experiment (19 male, 11 female,
mean age of 25) consisting of students from the University of Adelaide and members of the
general Adelaide population. All participants were required to be at least 18 years of age,
fluent in English, and have normal or corrected-to-normal vision. Participants were
incentivised by receiving a \$20 Coles/Myer gift card in exchange for their time (see
Appendix A). All participants provided informed consent prior to commencing the
experiment (see Appendix B).

Participants' responses were to be excluded if they failed to complete the experiment
due to illness, fatigue or excessive response delays (i.e., longer than the session allows).

Participants who responded in less than 500ms, or consecutively provided the same response,
for over 30 percent of trials were also to be excluded. In these cases, another participant was
to be recruited and given the same stimulus set according to the previous participant's
experiment number. None of the 30 participants met any of these pre-specified exclusion
criteria.

Power Analysis. To our knowledge, no previous research has analysed the effect of image presentation rate in a face recognition task. The sample size was determined based on a power analysis assuming a Smallest Effect Size of Interest (SESOI; Lakens, Scheel, Isagar, 2018) of d = 0.45 for all effects. Previous studies on face recognition typically show face

inversion effect sizes ranging between 0.96 and 1.29 (e.g., Civile, Elchlepp, McLaren, Galang,
Lavric, & McLaren, 2018), and so this SESOI was a conservative estimate. With a sample of
30 participants and 96 observations per participant (12 trials x 4 different image presentation
rates x 2 levels of image orientation = 96 trials), the experiment had an estimated power of
83.2% to detect a main effect of image presentation rate, and an estimated power of 98.2% to
detect an interaction between image presentation rate and orientation. We used Jake
Westfall's PANGEA R Shiny App to calculate power given these design parameters.

This experiment had a 4 (presentation rate: single image, 2, 4, 8 images per 256 second) x 2 (orientation: upright vs. inverted) fully within-subjects design. In Experiment 1, 257 participants were presented with a series of 96 face streams for eight seconds. Presentation 258 rate varied across the streams, with participants viewing streams of 64 face images for 125 250 milliseconds each (8 images per second), streams of 32 face images for 250 milliseconds each 260 (4 images per second), streams of 16 images for 500 milliseconds each (2 images per second), 261 and single images of faces for eight seconds. After a brief 500 millisecond delay, a new 'target' face image from either the same or different person was displayed and participants indicated on a scale whether they believed this new face was the same or different person as the face in the stream, and their confidence in their decision (see Figure 2).

The faces were presented upright for one half of the trials and inverted on the other half. Both orientation blocks were counterbalanced across participants. The four presentation rate blocks were also randomly presented to each participant within the two orientation blocks. Within each presentation rate block, half of the trials depicted the same person as the target image, and the other half depicted a different person to the target image. These trials were randomly presented for each participant.

[Figure 2]

Measures. Participants indicated their judgments on a 12-point forced choice confidence rating scale: 1 to 6 indicates a "Different" response and 7 to 12 a "Same"

response, with ratings closer to 1 and 12 indicating higher confidence than ratings closer to 6 or 7 (see Figure 2). This scale allows us to compute participants' accuracy (mean proportion correct), and mean confidence (between 1 and 6), and has been used in previous research to compute individuals' discriminability as indicated by the area under their proper Receiver Operating Characteristic (ROC) curve ('AUC'; Vokey, Tangen, & Cole, 2009).

To measure discriminability, we computed each participant's AUC for each condition 280 from their cumulative confidence ratings on same and different trials (see Hanley & McNeil, 281 1982; Vokey, 2016). An AUC of 1 indicates perfect discriminability, and an AUC of .5 282 indicates chance performance. A large number of 'hits' (i.e., participant correctly says 283 "Same") and a small number of 'false alarms' (i.e., participant incorrectly says "Same") 284 indicates high discriminability and would produce an AUC score closer to 1, whereas an 285 equal number of hits and false alarms would indicate chance discriminability, resulting in 286 lower AUC scores closer to .5. Participants' confidence is also taken into account in 287 computing AUC, such that lower confidence judgments reflect lower discriminability. 288

Confidence was computed by collapsing the 12-point rating scale to a 6-point scale.

280

The original scale provided six degrees of confidence for both "Different" (1-6) and "Same" 290 (7-12) responses; and so the collapsed scale isolates confidence by coding all "unsure" 291 responses (6 or 7) to 1, all "moderately unsure" responses (5 or 8) to 2, all "slightly unsure" 292 responses (4 or 9) to 3, and so on—until all "sure" responses (1 or 12) are coded to 6. 293 Materials. The faces were sourced from the VGGFace 2 dataset (Cao, Shen, Xie, 294 Parkhi, & Zisserman, 2018). The original set contains 3.31 million images of 9,131 identities collected from Google Image searches. We used a subset [add link] of 9,600 images of 48 identities (200 images per identity). We preserved all natural variation across the images of each identity to increase the difficulty of the target trials (i.e., dissimilar matching identities 298 are more challenging to tell together). The original dataset also contains a large number of 299 blonde, Caucasian, female identities. While this dataset has some limitations (which will be 300

addressed in the discussion), we constrained our subset to this demographic to increase 301 target-distractor similarity. Highly similar, non-matching identities are harder to tell apart; 302 and evidence suggests that female identites are typically perceived as more similar than male 303 identities (e.g., Ramsey et al., 2005). We further increased similarity by computing the 304 distributional characteristics (mean, min, max of image) of each identity and pairing similar 305 identities side-by-side to increase target-distractor resemblance (see Appendix C). 306

Ramsey, J. L., Langlois, J. H., & Marti, C. N. (2005). Infant categorization of faces: 307 Ladies first. Developmental Review, 25, 212–246. 308 https://doi-org.proxy.library.adelaide.edu.au/10.1016/j.dr.2005.01.001. 309

We reduced the original set of images for each identity down to 200 by manually 310 excluding any images with dimensions under 100 x 100 pixels, drawings, illustrations or 311 animations of faces, significantly occluded faces, faces with distracting watermarks, 312 duplicates or images that clearly depicted a different identity. All other original details were 313 left intact, including natural variation in pose, age, illumination, etc. We then cropped each 314 face to a square using a script in Adobe Photoshop CC (version 20.0.4) and centred the 315 images around the eyes as close as possible. To avoid ceiling effects for upright faces, we 316 initially reduced all the images to 64 x 64 pixels, then upsized them to 400 x 400 pixels in 317 MATLAB. However, after pilot testing (N = 2) revealed that the task was still too easy for 318 upright faces (mean proportion correct = .92), we further reduced the images to 32×32 319 pixels. A second pilot (N = 5) then revealed near-chance performance with the inverted 320 faces (mean proportion correct = .59), and so we generated a fresh batch of images reduced 321 to 48 x 48 pixels to avoid ceiling or chance performance in either condition (see Figure 2). 322 The video instructions and face recognition task were presented to 323 participants on a 13-inch MacBook Pro, with over-ear headphones. We developed the 324 software used to generate the trial sequences, present stimuli to participants, and record 325 their responses in LiveCode (version 9.0.2; the open source 'community edition'). The

326

LiveCode source files and experiment code are available in the Software component of the
OSF project. The data analytic scripts and plots for this project were produced in RStudio
with the R Markdown package. A list of other package dependencies needed to reproduce
our plots and analyses are listed in the data visualisation and analysis html file found in the
Analyses component of the OSF project.

Procedure. Participants commenced the task after reading an information sheet,
signing a consent form, and watching an instructional video [add link]. Participants rated a
total of 96 faces as the same or different identity to the faces in the stream. In each case,
they indicated their judgments on the 12-point confidence rating scale. The response buttons
remained on screen until participants selected their rating; however, a prompt to respond
within 4 seconds was displayed between trials if participants took longer to decide.
Corrective feedback in the form of an audio (correct or incorrect tone) and visual (the
selected response button turns green or red) cue is presented to participants after every trial.
The whole face recognition task took about 25 minutes to complete.

The following analysis examines participants' discriminability (AUC) scores and confidence. Raw proportion correct scores reflect the same pattern as discriminability, and can be found in the Appendix.

Presentation Rate and Orientation. We conducted repeated measures ANOVAs
on participants' AUC scores to test whether their ability to distinguish faces of the same
versus different identities significantly increased as presentation rate increased, and whether
these effects varied as a function of familiarity with the stimulus orientation. As shown in

Table 1, our results suggest that participants are better at recognising faces when viewing 353 rapid streams of the same face compared to single images for both upright and inverted 354 conditions, despite discriminability being lower overall with inverted faces compared to 355 upright faces. A repeated measures ANOVA vielded a significant, medium-to-large (see 356 Cohen, 1988 for conventions) main effect of orientation (F(1, 29) = 68.258, p < .001, G2 =357 .148) and a significant, small-to-medium main effect of image rate (F(3, 87) = 3.788, p =358 .013, G2 = .041) on participants' discriminability scores (see Figure 3). No significant 359 interaction was found (F(3, 87) = 1.952, p = .127, G2 = .019). A treatment-control contrast 360 suggested that when compared to viewing a single image, participants' discriminability 361 scores significantly improved under all rapid presentation rate conditions (2 images: t = 362 2.192, p = .029; 4 images: t = 2.468, p = .014; 8 images: t = 2.431, p = .016). A subsequent 363 trend analysis also revealed a significant linear trend over presentation rate conditions (t = 2.394, p = .018). That is, discriminability increased in a linear fashion as a function of increasing presentation rate for both upright and inverted faces, despite inverted faces being harder to recognise.

Mean Discriminability (AUC)					
Orientation	Image_Rate	mean	SD		
upright	1 image	0.548	0.216		
upright	2 images	0.715	0.242		
upright	4 images	0.698	0.208		
upright	8 images	0.684	0.176		
inverted	1 image	0.462	0.163		
inverted	2 images	0.473	0.202		
inverted	4 images	0.513	0.218		
inverted	8 images	0.524	0.201		

368

Mean Discriminability (PC)						
Orientation	Image_Rate	mean	SD			
upright	1 image	0.619	0.138			
upright	2 images	0.733	0.190			
upright	4 images	0.733	0.151			
upright	8 images	0.733	0.139			
inverted	1 image	0.542	0.117			
inverted	2 images	0.547	0.145			
inverted	4 images	0.625	0.143			
inverted	8 images	0.603	0.145			

[figure 3]

369

370

To address our prediction that confidence will be highest when viewing single images, 371 we analysed participants' confidence ratings for each condition. As shown in Table 2, 372 participants were more confident at identifying upright compared to inverted faces, though 373 confidence seems similar across different presentation rates. A repeated measures ANOVA 374 revealed a significant, medium-to-large main effect of orientation (F(1, 29) = 8.655, p = .006,375 G2 = .020), but no significant main effect of image rate (F(3, 87) = 0.785, p = .505, G2 = 376 (.002), and no significant interaction (F(3, 87) = 0.365, p = .779, G2 = .001; see Figure 4). 377 Given that confidence did not significantly differ across image rate conditions, our data did 378 not support the third hypothesis. 379

[table 2] [figure 4]

1 Discussion

380

Addressing Predictions. This experiment aimed to assess whether rapid exposure to many instances leads to better face recognition when presented with upright and inverted faces. In line with previous face-matching literature, our analyses suggest that this is indeed

the case. While previous research suggests that RSVP streams allow observers to recognise
the average representation of similar items (e.g., Ariely, 2001; De Fockert & Wolfenstein,
2009), the current study also suggests that this ensemble can facilitate the recognition of new
instances of the same category. This is not surprising, given that previous face recognition
research suggests that we compare new instances of a familiar face to the average
representation of that face in our long-term memory (e.g., Bruce & Young, 1986; Burton &
Bruce, 1993).

Our results also suggest that the benefit associated with increasing image rate occurred 392 in a similar manner for both upright and inverted faces, despite inverted faces being harder to recognise overall. While lower performance when recognising inverted faces was expected (see Tanaka & Simonyi, 2016, and Valentine, 1988), it is surprising that the RSVP paradigm 395 influenced both upright and inverted faces equally. Given that we already process upright 396 faces more successfully than inverted faces, we expected that upright image streams may 397 only provide a slight benefit over single images, compared to inverted faces, which may show 398 a larger benefit as image rate increased. Our results may be a product of presenting the 399 images at a reduced resolution to prevent ceiling effects. It is possible that this may have 400 lessened the upright face advantage (e.g., Balas, Gable, & Pearson, 2019), allowing the image 401 streams to demonstrate a effect for both orientation conditions. However, no studies seem to 402 have tested the face inversion effect at reduced resolutions, and so future research may wish 403 to confirm this conclusion. 404

I also suspected a lesser advantage for upright faces due to the flashed-face distortion effect (FFDE). The FFDE refers to the apparent distortion of upright (but not inverted) faces presented in an RSVP stream of different random faces, and is thought to emerge due to the relative differences between facial features contrasting from one identity to the next (Tangen et al., 2011). The lack of interaction between orientation conditions, however, suggests that the FFDE had no detrimental effect on either condition. Given that each face in the streams belonged to the same person in the current experiment, rather than different people as is typically the case with FFDE studies (e.g., Balas & Pearson, 2019; Bowden et al., 2019), it may be that the commonalities across each face image were exaggerated, rather than the differences, thereby increasing performance when viewing rapid streams. However, given that I did not directly manipulate the FFDE, future experiments may wish to explicitly measure the potential influence of this effect in similar face recognition tasks, to investigate whether it aids encoding of an unfamiliar face.

One minor limitation regarding the current methodology is that, given Limitations. 418 that the selected database sampled faces from Google Images, several of the identities 419 depicted celebrities. Although this provided a suitably large sample of naturally varying face images that could not be found in other databases, this may have increased participants' 421 performance in some trials and inflated our effect sizes, as familiar faces are easier to 422 recognise than unfamiliar faces (Megreya & Burton, 2006). However, given that recognising 423 celebrity faces is also impaired by the face inversion effect (references), and that most 424 participants self-reported being unfamiliar with the vast majority of identities (available in 425 the Data section of the OSF page) regardless, our results are unlikely to be significantly 426 impacted by this confound. Nevertheless, future research may wish to use a dataset 427 containing exclusively unfamiliar faces if one is available. 428

Another factor to consider is the possible interference of the own-race bias, given that 420 all our identities depicted Caucasian faces. However, while face processing and identification 430 may have suffered for non-Caucasian participants, our results do not seem to differ from 431 what we would expect with only Caucasian participants. True, being presented with an 432 other-race face would make single image identifications more difficult (references); however, 433 this is already a difficult task for own-race faces compared to multiple image identifications (reference), and so the relative performance with single images is expected. One might 435 presume that the own-race bias would have made it increasingly difficult to process faces at 436 more rapid image rates (reference); but if this was particularly influential, then we would not 437

have observed an overall linear increase in recognition as image rate increased. In fact, given that we observed our pattern of results even despite the own-race bias, this may argue towards the strength of this methodology in facilitating face identification.

Experiment 2

Experiment 1 suggests that presenting similar images in an RSVP stream can facilitate the identification of new instances even when viewing less familiar stimuli (e.g., inverted faces). This method of rapidly presenting multiple similar instances may also be useful in improving performance in other disciplines that rely on identifying naturally varying images—such as fingerprint examination (see Figure 5).

447 Method

In this experiment, participants viewed single images of a latent crime scene fingerprint
before viewing a stream of fingerprint images. They then determined whether the
fingerprints in the stream belonged to the same or different finger, or the same or different
person more broadly, to the latent fingerprint (see Figure 5 and Figure 6). As in Experiment
1, presentation rate varied for each stream, and participants' confidence and discriminability
were the main performance measures of interest. This experiment was preregistered along
with Experiment 1.

Participants. Both experiments were conducted concurrently with the same participants.

Design. Experiment 2 had a 4 (image presentation rate: single image, 2, 4, 8 images
per 8-second stream) x 2 (image specificity: prints from the same finger vs. prints from the
same person) fully within-subjects design. Participants judged if a latent fingerprint
belonged to the same or different finger or person as the fingerprint images in a rapidly
presented stream of images. In this experiment, participants viewed the latent fingerprint
(single image) before viewing the image stream. Due to the limited number of fingerprint
images in the selected dataset, streams consisted of one-second fingerprint streams presented

'on loop' for eight seconds. Participants viewed streams of eight images per second for 125 milliseconds each, streams of four images per second for 250 milliseconds each, streams of two images per second for 500 milliseconds each, and single fingerprint images for eight seconds. Fingerprint streams remained on-screen until a response was made, though participants were prompted to respond within eight seconds (see Figure 6). Participants received corrective feedback for every decision.

[figure 6]

470

Materials. The fingerprints were generated from a subset of the Forensic Informatics 471 Biometric Repository (Tear, Thompson, & Tangen, 2010). For the person recognition 472 component of the task, there are ten fully-rolled prints, one from each finger, from 48 473 different individuals. These served as the rolled prints presented in the rapid streams. For 474 each individual there is also one 'target' latent print from the same person, and a 'distractor' 475 latent print from another person. The targets and distractors were always taken from the left 476 thumb, as previous research suggests that novices can distinguish prints based on hand type 477 (less so based on finger type; Searston & Tangen, 2017a, 2017b; Thompson & Tangen, 2014). 478 For the finger recognition component of the task, there are eight different fully-rolled impressions from the left thumb of the same 48 individuals. The target and distractor latent prints are the same as those used in the person component of the task. 481

All natural variation in the latent prints was preserved, while the rolled prints
presented in the streams were centred on a white background, grey-scaled, level balanced,
and cropped to 400 x 400 pixels (as with the faces). Any distracting borders and text from
the arrest cards were removed to isolate the prints.

Software. The software for Experiment 2 was identical to that in Experiment 1. The relevant files are similarly available under the same pre-registration link.

Procedure. Participants were randomly assigned to complete Experiment 2 either immediately before or after Experiment 1. The procedure for Experiment 2 was identical to

that in Experiment 1, except for the necessary design changes, and participants were prompted to respond within eight seconds.

492 Results

[Report paired comparisons – and any other instances where significant differences would be unlike
The following analysis examines participants' discriminability (AUC) scores and confidence.
Raw proportion correct scores can be found in the Appendix.

Presentation Rate and Image Specificity. I conducted repeated measures 496 ANOVAs on participants' AUC scores to test whether their ability to distinguish related and 497 non-related fingerprints significantly increased as presentation rate increased, and whether these effects varied as a function of stimulus specificity level. As shown in Table 3, my results 499 show that participants' fingerprint recognition performance generally decreased as image rate increased for both "same finger" and "same person" conditions. My results suggest no significant main effect of specificity (F(1, 29) = 0.108, p = .744, G2 < .001), a significant, 502 small-to-moderate main effect of image rate (F(3, 87) = 3.367, p = .022, G2 = .035) on 503 participants' discriminability, and no significant interaction (F(3, 87) = 2.053, p = .112, G2)504 = .018; see Figure 7). Mauchly's test for sphericity suggests that the assumption of sphericity 505 was met (image rate: W = .934, p = .862; specificity-image rate interaction: W = .827, p = 506 .386); and so no corrections were applied to the reported p-values. A treatment-control 507 contrast suggested that compared to viewing a single image, participants' discriminability 508 scores significantly decreased when presented with 4 and 8 images per second (2 images: t =509 -0.897, p = .371; 4 images: t = -2.016, p = .045; 8 images: t = -2.663, p = .008). A 510 subsequent trend analysis also revealed a significant linear trend over presentation rate (t =511 -2.880; p = .004). That is, discriminability decreased in a linear fashion as presentation rate 512 increased for both same finger and same person conditions—contrary to my predictions. 513

To investigate my prediction that confidence will be highest when viewing single 515 images, I also examined participants' confidence ratings for each condition. As demonstrated 516 in Table 4, participants were consistently confident across all presentation rates when 517 viewing streams of prints from the same person and prints from the same finger. A repeated 518 measures ANOVA revealed no significant main effect of specificity (F(1,29) = 3.994, p =519 .055, G2 = .006) or image rate (F(3,87) = 0.763, p = .518, G2 = .002), and no significant 520 interaction (F(3,87) = 0.486, p = .693, G2 < .001; see Figure 8). Mauchly's test for 521 sphericity suggests that the assumption of sphericity was met (image rate: W = .743, p = 522 .144; specificity-image rate interaction: W=.676, p=.054); and so no corrections were 523 applied to the reported p-values. Given that confidence did not significantly differ across 524 image rate conditions, my data does not support my initial prediction. 525

[table 4] [figure 8]

7 Discussion

526

Addressing Predictions. This experiment aimed to assess whether viewing several 528 impressions of similar fingerprints, either from the same finger or the same person, would 529 better assist novices in making an identification compared to viewing a single fingerprint for 530 a longer duration. My results suggest that this is not the case for either condition. Since 531 novices have no experience in fingerprint matching, it is possible that recognition may 532 benefit from carefully assessing fingerprints, as is currently standard practice (e.g., Busey & 533 Parada, 2010), during the early stages of training. Indeed, given that understanding the 534 images in an RSVP stream seems to rely on holistically processing each image (i.e., perceiving a complex image as a whole, rather than a collection of features; see Oliva, 2005), which may depend on image familiarity (e.g., Tanaka & Simonyi, 2016), it may be that the 537 completely novel nature of the stimulus class required longer exposure to compensate for a 538 lack of holistic processing. If this is true, it is plausible that rapidly presenting fingerprints 539 may have introduced a floor effect in participants' performance—obscuring any positive

effect that viewing multiple exemplars may have otherwise exerted. This explanation seems likely, as discrimination performance significantly decreased as presentation rate dropped below 300 milliseconds per image—the approximated minimum duration required to process visual stimuli (Potter, 1976).

The fact that there was no significant difference or interaction between the same 545 person and same finger conditions was also surprising. We suspected that performance would 546 be higher when participants viewed streams from the same finger, to the extent that these 547 streams contain less variation compared those in the 'same person' condition and provided a more stable ensemble representation with which to compare the latent print (see Whitney & Leib, 2018). However, while no studies have directly compared the two conditions as in the 550 present experiment, evidence suggests that novices may not perform very differently when asked to match a print to either the same person or same finger (see Searston & Tangen, 2017c, Tangen et al., 2011, and Thompson et al., 2014). It seems likely, therefore, that 553 because novices have no specific fingerprint matching experience like experts, the RSVP 554 methodology allows them to notice general similarities between related prints, regardless of 555 how precisely the prints are related. 556

Future Directions. While the current results suggest that the RSVP paradigm 557 does not improve fingerprint novice performance, this does not necessarily mean that 558 exposure to various naturally varying fingerprints will not benefit novices. Previous research 559 suggests that images presented in streams of at least one second per image can be efficiently 560 remembered for long periods (e.g., Potter & Levy, 1969; Standing, 1973); and additionally, 561 Thompson and Tangen (2014, Experiment 3) suggested that viewing a print for two seconds only incurred a 6.8 percent decrease in accuracy for novices compared to viewing prints for one minute. It is possible, therefore, that if each fingerprint in the stream was presented for several seconds, rather than several milliseconds, this may optimally balance the advantages 565 of both viewing the detail in a single image and being exposed to variability within images. 566 Future research may wish to either decrease the presentation rate, or allow participants 567

themselves to control presentation rate and view each fingerprint for as long as they deem necessary for familiarisation. The latter manipulation would preserve individual differences in evidence accumulation styles (i.e., some people may prefer more image variation, while others may prefer more viewing time), providing a less intrusive method of investigating how presentation rate might predict identification performance.

Additionally, future research may wish to administer the current experiment to 573 participants with varying degrees of fingerprint-matching experience. Given that novices did 574 not benefit from the RSVP stream (and were no better than chance in some conditions), it is 575 possible that more experienced fingerprint examiners may derive greater benefits from the 576 RSVP paradigm, as they may process the fingerprints more holistically (Busey & 577 Vanderkolk, 2005; but see Vogelsang, Palmeri, & Busey, 2017 for a competing study). Given 578 that previous research suggests that the majority of learning among novices occurs within 579 the first three months of training (Searston & Tangen, 2017b), it is possible that increasing 580 exposure to varying prints may be most beneficial after the initial learning phase. 581

582 General Discussion

583

586

- what are the 3-5 main findings? (plan)
- brief overview of hypotheses and findings (8-10 sentences max) anything
 new/original?
 - few paragraphs dealing with the headline findings and relating it to literature

This thesis examined whether rapidly viewing several instances of complex stimuli,
across varying levels of familiarity (Experiment 1) and specificity (Experiment 2), would
better facilitate recognition of a new instance compared to viewing a single image for a
longer duration. Previous literature suggests that we can recognise new instances of an
object based on our prior experience with similar instances (Brooks, 1987; Medin & Ross,
1989). Research on ensemble coding also suggests that we can rapidly understand the

596

609

610

611

612

613

general nature of an object as we view several similar, varying instances (e.g., Im & Chong, 2009; Morgan et al., 2000). However, no research has examined how an RSVP-generated ensemble representation may assist in identifying new instances.

Experiment 1 suggests that ensemble coding may indeed facilitate recognition when

viewing upright and inverted faces. Given that upright and inverted faces differ only in 597 observers' decreased familiarity with inverted faces (Valentine, 1988), these results suggest 598 that ensemble coding may assist recognition even when exposed to less familiar stimuli. 590 Experiment 2, however, suggests the opposite pattern of results, as fingerprints—a completely 600 unfamiliar stimulus class—showed worse discrimination when participants were presented 601 with RSVP streams from either the same finger or same person as the crime scene print. 602 **Addressing Predictions.** Contrary to my predictions in both experiments, 603 participants' confidence showed no significant differences across image rate conditions, 604 despite single images allowing the greatest encoding time. It may be that the task demands 605 were too difficult in each condition for participants to feel confident. Indeed, identifying 606 different instances of unfamiliar faces has been reported to be a challenging task (e.g., Bruce 607 et al., 1999), which would undoubtedly be harder when the faces are blurred (e.g., Balas et 608

al., 2019; Sanford, Sarker, & Bernier, 2018); and novice performance in fingerprint matching

appears equally challenging (Searston & Tangen, 2017c; Tangen et al., 2011; Thompson et

variation with single images compared to less processing time with several images) may have

al., 2014). It seems likely that the relative disadvantages in either condition (i.e., less

undermined confidence equally across all conditions.

Discrepancies Between Discriminability Patterns. Although my contradicting
discriminability results between the two experiments were unexpected, several explanations
are possible. Firstly, the presentation of the test stimulus in Experiment 2 before, rather
than after the image streams, may have placed greater demands on working memory. This
may have made Experiment 2 more difficult than Experiment 1, particularly as the images
became more difficult to process at faster image rates. The fact that ensemble coding seems

more beneficial during the encoding stage of learning an identity, rather than on retrieval,
seems consistent with previous research, which typically suggests that we can identify a new
image by comparing its similarity to previously encountered images or representations (e.g.,
Brooks, 1987; Dopkins & Gleason, 1997). If participants can only view similar instances after
being exposed to the test stimulus, as in Experiment 2, then they are not previously
encountering similar instances to create a representation; they view these images after the
fact.

A second possible explanation is that compared to faces, fingerprints may be too 627 difficult for novices to process using the current methodology. Although Experiment 1 628 suggests that RSVP streams may familiarise observers with less familiar stimuli (i.e., inverted faces), fingerprints may simply be too unfamiliar for a similar benefit to occur. Although no study seems to have obtained reliable results comparing novice performance with fingerprints and inverted faces (see Searston & Tangen, 2017 - task vs. class), our daily 632 exposure to faces and innate ability to process face-like objects may nevertheless make face 633 processing easier than fingerprints. Previous research suggests that as an image category 634 becomes less familiar, the category is processed less holistically (e.g., Campbell & Tanaka, 635 2018; Wong et al., 2009). Given that the RSVP methodology seems to depend somewhat on 636 holistic processing and gist perception (see Oliva, 2005), it is possible that the completely 637 unfamiliar nature of fingerprints reduces any potential benefit of the RSVP stream -638 particularly as image rate increases. Previous research suggests that holistic and analytic 639 processing seem to be opposing ends of a spectrum, rather than a dichotomy (see Farah, 640 1992, and Tanaka & Simonyi, 2016) - and if this is the case, future research that wishes to 641 use this methodology for identification tasks may wish to adjust the image rate to suit the 642 relative unfamiliarity of the selected image category. 643

Discrepancies Between Chance Comparisons. While participants in both experiments displayed better performance than chance, participants in Experiment 1 displayed a higher difference (d = 0.121) than those in Experiment 2 (d = 0.058). In

addition to the changes listed above, this difference in overall discriminability may be due to 647 the fact that Experiment 1 had a higher degree of image variation than Experiment 2. In 648 Experiment 1, all images were coloured and blurred and consisted of people in different 649 contexts, including the subsequent test images; however, in Experiment 2 the stream images 650 were somewhat controlled and artificial (i.e., fully-rolled prints, all on a white background) 651 compared to the latent crime scene prints, which may vary in different ways to the prints 652 used in the stream (e.g., contact surface or print pressure). That is, the streams in 653 Experiment 1 were a closer match to the test images than in Experiment 2. Previous 654 research in face recognition suggests that exposure to more variable images better facilitates 655 recognition in a new context compared to less variable images (Menon, White, & Kemp, 656 2015; Ritchie & Burton, 2017), and so it is possible that the more controlled nature of the 657 stream images in Experiment 2 may have hindered participants' ability to recognise the test images compared to the more variable stream images in Experiment 1. However, Ritchie and Burton (2017) suggest that [viewing multiple similar images, even with (?)] reduced variability should nevertheless increase rather than decrease recognition compared to viewing 661 single images. As such, while reduced variability may explain why participants did not 662 benefit from the print streams in Experiment 2, it does not account for the significant 663 decrease in discriminability observed with increasing presentation rates. Of course, it is 664 possible that a combination of the aforementioned design factors may have produced the 665 opposite trends observed across the two experiments. 666

Another possible factor that may have contributed to the different pattern of results across the two experiments is that Experiment 2 contained fewer unique image exemplars in the streams compared to those in Experiment 1. Given the differences in the selected databases, participants viewed fewer unique fingerprints in each stream compared to the faces in Experiment 1. Indeed, even the highest presentation rate condition in Experiment 2 only showed participants eight unique prints, compared to the slowest stream condition in Experiment 1, which contained 16 unique faces. Given that previous research suggests that

viewing fewer different exemplars may decrease recognition of new instances compared to 674 viewing more (Murphy et al., 2015), it is possible that there were not enough fingerprints to 675 produce a similar benefit of presentation rate in Experiment 2. However, it is also important 676 to note that, in real-world fingerprint examination settings, examiners are unlikely to always 677 have access to many varying exemplars of a suspects' fingerprints—in some cases, fingerprint 678 databases may only contain a single comparison print, or a ten-print card consisting of 679 fully-rolled prints and 'slapped' prints from the same person, and not the same finger (Jain, 680 Nandakumar, & Ross, in press; PCAST, 2016). While Experiment 2 aimed to use prints that 681 fingerprint analysts are likely to encounter in their daily work (e.g., latent crime scene prints 682 presented with fully rolled suspect prints), and the aforementioned task constraints are an 683 important limitation with respect to the experiment's theoretical implications, they also 684 highlight real constraints in attempting to generalise these findings to more applied contexts.

Broader Implications. While the current study sheds light on our ability to 686 identify new instances of unfamiliar images, using images commonly used by forensic 687 examiners, this methodology cannot be directly extrapolated into every forensic case. The 688 number of images available to forensic examiners for any given identity and category may 689 drastically limit how applicable this methodology can be to real cases - for example, 690 fingerprint examiners typically would not have access to so many fully-rolled prints from the 691 same finger for any given suspect. That is not to say, however, that this methodology cannot 692 be used to improve forensic identification training in a number of disciplines. 693

- increasing exposure to several varying exemplars (albeit at a slower rate) may improve novices' experience with a given category, and simulate expertise more quickly over time
- 697

694

695

696

Despite the different pattern of results observed with faces and fingerprints, my findings nevertheless help reveal important information about how observers may best

familiarise themselves with novel images under different conditions. If these findings were to be replicated or extended in different contexts, they may reveal benefits of image 701 presentation rate beyond face recognition for other domains of perceptual expertise. Given 702 that prior exposure to variation seems to increase recognition performance when controlling 703 for time, the identification decisions of counterfeit investigators, passport officers, various 704 medical practitioners, and other professionals who rely on their perceptual expertise, may 705 benefit from accumulating as much exposure as possible to varying examples within their 706 domain. Future research may look to improve expert identification decisions by optimising 707 the advantages of viewing time and exposure to variation in a range of given fields. 708

• Experts (e.g., fingerprints, antique cars) struggle to identify things too far from their domain of expertise... possible that exp 2 will yield different results depending on whether we test experts or not

712 Conclusion

709

710

711

This thesis is the first to explore how to best familiarise observers with complex, 713 unfamiliar images given a fixed amount of time: should we assess the finer details, or glean 714 the general gist of several similar images? Across two experiments, I establish a new 715 relationship between the RSVP-based ensemble coding literature and the image recognition 716 literature, with the caveat that this relationship may change when presented under different 717 conditions and in other expert domains not explored in this thesis. In Experiment 2, I 718 attempted to boost novices' fingerprint identification performance by increasing their 719 exposure to fingerprint variation in each case, and I found tentative support for current analytical practices, as reported by analysts, during the early stages of their training. My 721 thesis highlights the need to further investigate how to optimally balance the potential advantages of both assessing the details of individual instances, and gaining experience with 723 natural variation, when tasked with recognising familiar or unfamiliar identities and visual 724 categories. As it stands, this thesis provides foundational evidence for the effect of 725

- presentation rate that may inform future research on improving the training and
- 127 identification decisions of professionals in medicine, security, and law enforcement—who are
- faced with the task of diagnosing or classifying new complex cases based on their previous
- experience.
